(Received 7 September 2012; published 4 December 2012)

Bismuth ($^{209}$Bi) is the deepest group V donor in silicon and possesses the most extreme characteristics such as a $9/2$ nuclear spin and a 1.5 GHz hyperfine coupling. These lead to several potential advantages for a Si:Bi donor electron spin qubit compared to the more common phosphorus donor. Most previous studies on Si:Bi have been performed using natural silicon where linewidths and electron spin coherence times are limited by the presence of $^{29}$Si impurities. Here, we describe electron spin resonance (ESR) and electron nuclear double resonance (ENDOR) studies on $^{209}$Bi in isotopically pure $^{28}$Si. ESR and ENDOR linewidths, transition probabilities, and coherence times are understood in terms of the spin Hamiltonian parameters showing a dependence on field and $m_I$ of the $^{209}$Bi nuclear spin. We explore various decoherence mechanisms applicable to the donor electron spin, measuring coherence times up to 700 ms at 1.7 K at X band, comparable with $^{28}$Si:P. Importantly, the coherence times we measure follow closely to the calculated field gradients of the transition frequencies ($df/dB$), providing a strong motivation to explore “clock” transitions where coherence lifetimes could be further enhanced.

I. INTRODUCTION

Amongst the first proposals for quantum information processing (QIP) in solid state devices was that by Kane in 1998, using phosphorus (P) dopants in silicon, the first of the group V donors.1 The choice of the P dopant, in particular, can be attributed to its use in classical silicon technology as donors, in addition to the simplicity of the spin system, which consists of an electron and nuclear spin 1/2. Si:P has been extensively studied as a potential qubit2,3 and is more than ever one of the leading candidates in the quest for a solid-state quantum computer.4,5 It begs the question, however, of whether the electron spin, where the transition frequency between two states is insensitive to first order in magnetic field fluctuations of the environment,14–16 on the other hand, high vapour pressure and low solubility of the donor in silicon complicates the doping process during growth,17 while the high atomic weight (209) increases defect density during ion implantation.11

II. MATERIALS AND METHODS

Most previous works7–10 on bismuth were realized using doped natural silicon crystals where the presence of other silicon isotopes, in particular, $^{29}$Si with a nuclear spin of 1/2, resulted in spectral broadening and coherence times limited to about 1 ms. We investigate here isotopically pure $^{28}$Si crystals,18 where the Bi was introduced during crystal growth using the method developed earlier for natural Si.17 The residual concentration of $^{28}$Si is 50 ppm, allowing us to explore the intrinsic properties of the bismuth donor electron spin in silicon. Pulsed electron spin resonance (ESR) experiments were performed using a X band (9.74 GHz) Bruker Elexsys E680 and E580 spectrometers. Unless otherwise mentioned, the concentration of activated Bi is $2 \times 10^{15}$ cm$^{-3}$.

III. ESR AND ENDOR SPECTRUM

The bismuth donor coupled nuclear/electron spin system is described in frequency units by an isotropic spin Hamiltonian:

$$H_0 = B_0(y_E S_z \otimes I_z + y_N I_z \otimes I_z) + A S \cdot I,$$

(1)

where the two first terms correspond to the electronic ($S$) and nuclear ($I$) Zeeman interactions with an external field $B_0$ and the last term corresponds to the hyperfine coupling $A$ (see Fig. 1). In addition to the normal ESR-allowed transitions ($|\Delta m_S = \pm 1, \Delta m_I = 0\rangle$), eight “forbidden” transitions ($|\Delta m_S = \pm 1, \Delta m_I = \mp 2\rangle$) can be found at the lower field side of the ESR lines for $-7/2 < m_I < +7/2$ [see Fig. 2(a)]. The separation between allowed
and forbidden peaks increases from $-30 \mu T$ for $m_I = +7/2$ to $-270 \mu T$ for $m_I = -7/2$. Simulations using EASYSPIN confirm the non-negligible intensity of these forbidden transitions, especially for low $|m_I|$ values that are the most mixed in terms of $m_5$ and $m_I$. An electron spin echo (ESE) intensity ratio between the allowed/forbidden transitions of nearly 0.25 was measured after optimization of the microwave power to each. Therefore these forbidden transitions offer an additional way to manipulate more states of the 20 dimensional Hilbert space.

These $|\Delta m_I| = 2$ transitions were not observed in earlier studies using $^{29}$Si:Bi because unresolved hyperfine coupling to the surrounding $^{29}$Si broadens the ESR lines to about 0.4 mT. In contrast, the continuous wave (CW)-ESR linewidths in $^{28}$Si:Bi vary between 8.2 $\mu T$ and 22 $\mu T$ [see Fig. 2(b)]. Their $m_I$ dependence can be explained by a full width at half maximum (FWHM) hyperfine distribution between 40 and 90 kHz (depending on the sample) and a static $B_0$ field inhomogeneity about 3 $\mu T$ (a typical value for ESR). The hyperfine spread corresponds to about 30 ppm of the total value and arises most likely from lattice strains. Indeed, measurement of etch pit density after chemical etching showed dislocation densities between 2 and $6 \times 10^4$ cm$^{-2}$, depending on the sample. Figure 2(c) shows electron-nuclear double resonance (ENDOR) linewidths measured for about half of the 36 transitions. These can be explained by the same distribution in the hyperfine coupling $A$ (the $B_0$ inhomogeneity has negligible influence on the ENDOR linewidth).

**IV. EFFECT OF $df/dB$ ON ELECTRON SPIN DECOHERENCE**

The electron spin coherence time $T_{2e}$ was measured using a Hahn echo to eliminate the effect of static inhomogeneities. Using this method, a $T_{2e}$ of 20 ms can be measured at 5 K, however this technique adds its own type of decoherence to the system known as instantaneous diffusion (ID). The microwave $\pi$-pulse in the $\pi/2-\pi$-echo sequence flips all the spins in the sample, creating a change in the local magnetic field experienced by each spin. This additional dephasing mechanism, purely experimental, can be reduced by shortening the $\pi$ flip to a smaller tip-angle rotation, at the cost of less signal/noise. By extrapolation to a tip angle of zero, the intrinsic $T_{2e,\text{int}}$ can be found:

$$\frac{1}{T_{2e}} = \frac{1}{T_{2e,\text{int}}} + C (2\pi \gamma_{\text{eff}})^2 \frac{\pi}{9\sqrt{3}} \mu_0 h \sin \left(\frac{\theta}{2}\right)^2 \cdot (2)$$

where $\theta$ is the tip angle of the second microwave pulse and $C$ is the effective spin concentration (1/10th of the actual donor concentration as only one out of the 10 ESR lines is excited by a given pulse and participates in ID). $\gamma_{\text{eff}}$ is the effective gyromagnetic ratio, equal to $df/dB$, the gradient of the transition frequency with respect to the magnetic field. It represents both the sensitivity of the spin to the environment and its magnetic dipole strength.

For each sample with a given Bi donor concentration, we measured $T_{2e}$ as a function of tip angle for each of the different $m_I$ [inset in Fig. 3(a)], and fit the results to Eq. (2) with a single concentration $C$ and $\gamma_{\text{eff}}$ for each $m_I$ as fitting parameters. In all cases, the best-fit value of $C$ matched that extracted from electrical resistivity measurements to within...
FIG. 3. (Color online) Measurements of $T_{2e,\text{diff}}$ for the ten ESR transitions in Si:Bi. (a) ID slopes resulting from the fit of $T_{2e}$ times obtained using $\pi, \pi/2, \pi/4$ and $\pi/8$ pulses as measured at 5 K for each $m_I$ (some examples are shown in inset). The slopes vary according to $(df/dB)^2$, as expected from dipole-dipole interactions between neighboring Bi electron spins. (b) Extrapolated $T_{2e,\text{diff}}$ from the fit in (a) in the limit where $\theta \rightarrow 0$. The model shown in blue takes into account various sources of fluctuating magnetic field. In the fit, $\alpha = 0.15$ nT and $\beta = 0.023$ nT$^2$/Hz such that $\beta'(28)\beta^{28}$ varies from 0.27 to 0.57 nT. 10%. The fitted values for $\gamma_{\text{eff}}$ are shown in Fig. 3(a) and are in excellent agreement with the theoretical $df/dB$ for each transition, as calculated from the spin Hamiltonian in Eq. (1).

In addition to the slope, the intercepts at zero tip angle were also extracted from the fit providing the extrapolated $T_{2e,\text{int}}$, which are summarized in Figs. 3 and 4 as a function of $m_I$, temperature and donor concentration.

The different values for $df/dB$ for the ten ESR lines of Si:Bi offer an ideal opportunity to explore the contributions of decoherence mechanisms for donor electron spins in silicon, as studied previously in $^{28}$Si:P $^{2}$. $T_{2e}$ is limited directly by $T_{1e}$ above about 9 K, while below this temperature decoherence is driven by spin flips ($T_{1e}$) or energy-conserving flip flops of neighboring donor electron spins. Under both of these mechanisms, the effect on decoherence of a central spin is the product of both the sensitivity $df/dB$ of the central spin and the effective fluctuating magnetic field produced by neighboring spins. This effective field is related to the magnetic dipole strength of the neighbours, $df/dB$, however, since each neighboring donor can be in any one of ten $m_I$ states, the relevant $df/dB$ value must be averaged over different $m_I$ at the particular value of the applied magnetic field $B_0$. Therefore the effect of ($T_{1e}$) spin flips of neighbors can be simply modelled by an average dipole strength $(df/dB)$. On the other hand, the effect of flip flops between neighbours is the average product of the flip-flop rate and the magnetic field strength.

At X band, calculations show that this contribution has a similar trend to $T_{1e}$ of neighbours. In summary, the overall decoherence rate can be expressed as

$$\frac{1}{T_{2e,\text{int}}} = \frac{df}{dB} \times \left( \alpha + \beta \left( \frac{df}{dB} \right) \right), \quad (3)$$

where $\alpha$ is an additional field fluctuation, possibly from the external magnet, and $\beta$ represents both neighbor-$T_{1e}$ and flip-flop mechanisms as they are indistinguishable here. This is in excellent agreement with the observed experimental $m_I$ dependence of $T_{2e,\text{int}}$, shown in Fig. 3(b) at 5 K.

The temperature dependence of $T_{2e,\text{int}}$ in Fig. 4(a) arises from the combination of the (temperature independent) neighbor flip-flop process and the (strongly temperature dependent) $T_{1e}$. The latter appears twice in the sum of rates which determine $T_{2e}$: directly as $T_{1e}$ for spin flips of the central spin and as $\sqrt{T_{1e}}$ for spin flips of the neighbours. $T_{1e}$ is independent of concentration for small donor concentrations. As temperature decreases, $T_{1e}$ increases above seconds and neighbor flip flops become the limiting factor for coherence.
By fitting the temperature dependence of $T_{2e}$ according to the mechanisms above, we extract a low-temperature limit of $T_{2e}$, corresponding to the neighbor flip-flop mechanism, and plot this time in Fig. 4(b) against concentration for the three samples we have studied here. For comparison, $^{28}$Si:P values from Ref. 2 under similar experimental conditions are also shown.

For concentrations above a few $10^{14}$ cm$^{-3}$, the effect of flip-flops play a limiting role in $T_{2e}$, which follows a quadratic dependence on concentration. This dependence can be understood by considering that concentration affects both the flip-flop rate, and the sensitivity of the central spin to a neighbor flip flop. At lower concentrations, the effect of residual $^{29}$Si impurities becomes non-negligible and limits the coherence time to about 2 s. The difference in sensitivity to $^{29}$Si spectral diffusion between Bi and P can be accounted for, within experimental errors, by the difference in $df/dB$ (a factor of 0.65).

The average dipole coupling rate between two nearest neighbor Bi donor electron spins is about 10 Hz for a donor concentration of $10^{15}$ cm$^{-3}$. In contrast, the ESR linewidth is due to inhomogeneity in both $B_0$ and $A$ corresponding to broadening of about 60 and 200 kHz, respectively. Both of these linewidths are much greater than the dipole coupling rate and would largely suppress any nearest neighbor flip flops if they arose from inhomogeneity across a length scale comparable to donor-donor separation. For this reason, we conclude that the observed spread in hyperfine coupling strength $A$ derives from long-distance variations during the crystal growth process, consistent with strain fields from dislocations. Finally, coherence times and linewidths measured at the allowed transitions were similar at the forbidden transitions, as expected from nearly equal values of $df/dB$ and $df/dA$.

The temperature dependence of $T_{1e}$ for Si:Bi was studied by Belli et al., and found to be driven by an Orbach process above 25 K. Below this temperature, a first-order $T^{-7}$ Raman process has been suggested in recent papers, however, we find that a $T^{-9}$ Raman process from the spin-orbit interaction to be a better fit. The former process ($T^{-7}$) is expected to be frequency-dependent ($T_{1e} \propto f^{-2}$) while the latter ($T^{-9}$) has no frequency dependence.

We have measured a $T_{2e}$ time of Bi donors in $^{28}$Si of up to 700 ms at 1.7 K (using a refocussing pulse of angle $0.08\pi$ radians), comparable with that for P donors. Throughout this study of the various decoherence mechanisms present in $^{28}$Si:Bi, we have observed that the electron spin decoherence rates follow $df/dB$ to at least first order. This provides a motivation to study $T_{2e}$ at various clock transitions present in the range 5.2–7.3 GHz, at which $df/dB$ drops to zero. At these points, we would expect $T_{2e}$ to have a greatly reduced sensitivity to donor or $^{29}$Si concentration and approach the fundamental limit of $T_{1e}$, which exceeds one second below 6 K.

**V. CONCLUSIONS**

We have measured a $T_{2e}$ time of Bi donors in $^{28}$Si of up to 700 ms at 1.7 K (using a refocussing pulse of angle $0.08\pi$ radians), comparable with that for P donors. Throughout this study of the various decoherence mechanisms present in $^{28}$Si:Bi, we have observed that the electron spin decoherence rates follow $df/dB$ to at least first order. This provides a motivation to study $T_{2e}$ at various clock transitions present in the range 5.2–7.3 GHz, at which $df/dB$ drops to zero. At these points, we would expect $T_{2e}$ to have a greatly reduced sensitivity to donor or $^{29}$Si concentration and approach the fundamental limit of $T_{1e}$, which exceeds one second below 6 K.

DECOHERENCE MECHANISMS OF $^{209}$Bi DONOR ... PHYSICAL REVIEW B 86, 245301 (2012)

24A second effect of small tip angles is to reduce decoherence from so-called “direct” flip flops between a central Bi spin and one of its neighbors (as the probability of flipping both spins is low, the applied microwave pulse refocuses the flip flop).
