## **Abstract**

This paper estimates the marginal returns to college for individuals induced to enroll in college by a marginal policy change. The recent literature on instrumental variables estimation of the returns to college seeks to estimate this parameter, but in general it does so only under strong assumptions. We show how to utilize economic theory and local instrumental variables estimators to answer policy questions. Our empirical analysis shows that returns are higher for individuals more likely to attend college. We contrast the returns to well-defined marginal policy changes with IV estimates of the return to schooling.

JEL Code: J31

Key words: Returns to Schooling; Marginal Return; Average Return; Marginal Treatment Effect

# 1 Introduction

Estimating the marginal return to a policy is a central task of economic cost-benefit analysis. A comparison between marginal benefits and marginal costs determines the optimal size of a social program. For example, to evaluate the optimality of a policy that promotes expansion in college attendance, analysts need to estimate the return to college for the marginal student, against which to compare the marginal cost of the policy.

This is a relatively simple task (a) if the effect of the policy is the same for everyone (conditional on observed variables) or (b) if the effect of the policy varies across individuals given observed variables but agents either do not know their idiosyncratic returns to the policy, or if they know them, they do not act on them. In these cases, individuals do not choose their schooling based on how high their realized idiosyncratic individual returns are. The marginal and average ex post returns to schooling are the same.<sup>1</sup>

Under these conditions, the mean marginal return to college can be estimated using conventional methods applied to the following Mincer equation:

$$Y = \alpha + \beta S + \varepsilon, \tag{1}$$

where  $Y$  is the log wage,  $S$  is a dummy variable indicating college attendance,  $\beta$  is the return to schooling (which may vary among persons) and  $\varepsilon$  is a residual. The standard problem of selection bias ( $S$  correlated with  $\varepsilon$ ) may be present, but this problem can be solved by a variety of conventional methods (instrumental variables, regression discontinuity, and selection models).

The recent literature shows how to empirically test the conditions that justify conventional methods (Heckman, Schmierer, and Urzua, 2009). Applying these methods on data from the National Longitudinal Survey of Youth of 1979 (NLSY), we find that returns vary (i.e.  $\beta$  is random) and furthermore agents act on some knowledge of their idiosyncratic return (i.e.,  $\beta$  is correlated with  $S$ ). Selection on gains complicates the estimation of marginal returns.

Under assumptions given in Imbens and Angrist (1994), an instrumental variable estimator identifies a Local Average Treatment Effect (LATE), which measures the return to college for individuals induced to go to school by the change in the instrument. Unfortunately, the people induced to go to school by a change in an instrument need not be the same as the people induced to go to school by a given policy, and the returns to the two groups of people may differ. This paper shows how to use a version of instrumental variables introduced in Heckman and Vytlačil (1999, 2005, 2007b) to estimate the marginal returns to alternative ways of producing marginal expansions in college attendance when the variation in the available instruments do not correspond

---

<sup>1</sup>See Heckman and Vytlačil (2007b).

exactly to the variation induced by a policy.

For a sample of white males from the NLSY, we establish that marginal expansions in college attendance attract students with lower returns than those enjoyed by persons currently attending college. The contrast between what conventional IV measures and the marginal return to a policy can be stark. For example, while the conventional IV estimate is 0.0951, the estimated marginal return to a policy that expands each individual’s probability of attending college by the same proportion is only 0.0148.

The methods used in this paper improve on LATE by identifying what sections of an economically interpretable mean marginal benefit surface are identified by different instruments. It is thus possible to compare on a common scale the different margins identified by different instruments. Furthermore, the methods allow the evaluation of policy changes that don’t directly correspond to current variation in a particular instrument and are thus not directly identified by instrumental variables.

The plan of this paper is as follows. In the next section, we present the empirical framework used in this paper. The following section discusses the estimation method and presents empirical estimates and robustness checks. The final section concludes.

## 2 Methods for Estimating Marginal Returns

The generalized Roy Model is a basic choice-theoretic framework for policy analysis.<sup>2</sup> Let  $Y_1$  be the potential log wage if the individual were to attend college, and  $Y_0$  the potential log wage if the individual were not to attend college.<sup>3</sup> Define potential outcomes as

$$Y_1 = \mu_1(X) + U_1 \text{ and } Y_0 = \mu_0(X) + U_0, \tag{2}$$

where  $\mu_1(x) \equiv E(Y_1 | X = x)$  and  $\mu_0(x) \equiv E(Y_0 | X = x)$ . The return to schooling is  $Y_1 - Y_0 = \beta = \mu_1(X) - \mu_0(X) + U_1 - U_0$ , so that the average treatment effect conditional on  $X = x$  is given by  $\bar{\beta}(x) = E(\beta | X = x) = \mu_1(x) - \mu_0(x)$  and the average effect of treatment on those who choose to attend college conditional on  $X = x$  is given by  $E(\beta | X = x, S = 1) = \bar{\beta}(x) + E(U_1 - U_0 | S = 1, X = x)$ .  $X$  need not be statistically independent of  $(U_0, U_1)$  for our identification analysis. We condition on  $X$  throughout.

---

<sup>2</sup>The model originates in the work of Roy (1951) and Quandt (1958, 1972). See, e.g., Heckman and Vytlačil (2007a) for a discussion of the model, its origins, and its wide uses in economics.

<sup>3</sup>We reduce schooling choices to two levels, as in Willis and Rosen (1979), Taber (2001), or Moffitt (2009). Heckman and Vytlačil (2007b) and Heckman, Urzua, and Vytlačil (2006, 2009) present methods for multiple schooling levels. We annualize our estimates by dividing them by the difference in the average years of schooling of individuals in each group. Since this is a potentially important restriction, in the empirical work reported below we present results using alternative definitions of schooling.

A standard latent variable discrete choice model represents the individual’s decision to enroll in college (see, e.g., Willis and Rosen, 1979). Let  $I_S$  be the net benefit to the individual of enrolling in college, which depends on observed ( $Z$ ) and unobserved ( $V$ ) variables:

$$\begin{aligned} I_S &= \mu_S(Z) - V, \\ S &= 1 \text{ if } I_S \geq 0; S = 0 \text{ otherwise.} \end{aligned} \tag{3}$$

A person goes to college ( $S = 1$ ) if  $I_S \geq 0$ ; otherwise  $S = 0$ . In this notation, the analyst observes  $(Z, X)$  but not  $(U_0, U_1, V)$ .  $V$  is assumed to be a continuous random variable with a strictly increasing distribution function  $F_V$ .  $V$  may depend on  $U_1$  and  $U_0$  in a general way. The  $Z$  vector may include some or all of the components of  $X$ , but it also includes variables excluded from equation (2) (i.e., excluded from  $X$ ). We assume that  $(U_0, U_1, V)$  is independent of  $Z$  given  $X$ . The additive separability between  $Z$  and  $V$  in the latent index plays an essential role in the instrumental variables literature. Model (3) with  $Z$  independent of  $(U_0, U_1, V)$  given  $X$  implies and is implied by the Imbens-Angrist independence and “monotonicity” assumptions (see Vytlacil, 2002).

Let  $P(z)$  denote the probability of attending college ( $S = 1$ ) conditional on  $Z = z$ ,  $P(z) \equiv \Pr(S = 1 | Z = z) = F_V(\mu_S(z))$ , where we keep the conditioning on  $X$  implicit.  $P(z)$  is sometimes called the propensity score. Define  $U_S = F_V(V)$ . It is uniformly distributed by construction, and different values of  $U_S$  correspond to different quantiles of  $V$ . We can rewrite (3) using  $F_V(\mu_S(Z)) = P(Z)$  so that  $S = 1$  if  $P(Z) \geq U_S$ .  $P(Z)$  is the mean scale utility function in discrete choice theory (McFadden, 1974).

The marginal treatment effect (MTE), defined by

$$\text{MTE}(x, u_S) \equiv E(\beta | X = x, U_S = u_S),$$

is central to our analysis of how to go from (local) IV estimates to policy effects. This parameter was introduced in the literature by Björklund and Moffitt (1987) and extended in Heckman and Vytlacil (1999, 2001a, 2005, 2007b). It is the mean return to schooling for individuals with characteristics  $X = x$  and  $U_S = u_S$ . Recall that  $U_S$  has been normalized to be unit uniform, so that tracing MTE over  $u_S$  values shows how the returns to schooling vary with different quantiles of the unobserved component of the desire to go to college. Alternatively, it is the mean return to schooling for persons indifferent between going to college or not who have mean scale utility value  $P(Z) = u_S$ .

The MTE can be estimated by the method of local instrumental variables (Heckman and Vytlacil, 1999, 2001a, 2005), which we implement in this paper. It is identified by differentiating  $E(Y | X = x, P(Z) = p)$  with respect to  $p$ , which can be computed over the support of the

distribution of  $P(Z)$ . Using the equations in (2), observed earnings are

$$\begin{aligned} Y &= (S)Y_1 + (1 - S)Y_0 = \mu_0(X) + [\mu_1(X) - \mu_0(X) + U_1 - U_0]S + U_0 \\ &= \mu_0(X) + [\mu_1(X) - \mu_0(X)]S + \{U_0 + S(U_1 - U_0)\}. \end{aligned} \quad (4)$$

The conditional expectation of  $Y$  given  $X = x$  and  $P(Z) = p$  is

$$E(Y | X = x, P(Z) = p) = E(Y_0 | X = x, P(Z) = p) + E(Y_1 - Y_0 | X = x, S = 1, P(Z) = p)p.$$

Using choice equation (3), this expression as can be written as

$$\begin{aligned} E(Y | X = x, P(Z) = p) & \quad (5) \\ &= \mu_0(x) + [\mu_1(x) - \mu_0(x)]p + \int_{-\infty}^{\infty} \int_0^p (u_1 - u_0)f(u_1 - u_0 | X = x, U_S = u_S) du_S d(u_1 - u_0), \end{aligned}$$

where  $f(u_1 - u_0 | X = x, U_S = u_S)$  is the conditional density of  $U_1 - U_0$ .<sup>4</sup> Simplifying the expression, we can rewrite it as

$$E(Y | X = x, P(Z) = p) = \mu_0(x) + \int_0^p \text{MTE}(x, u_S) du_S.$$

The left-hand side of this expression can be consistently estimated from sample data. Differentiating with respect to  $p$ , we obtain the MTE:

$$\frac{\partial E(Y | X = x, P(Z) = p)}{\partial p} = \text{MTE}(x, p). \quad (6)$$

Applied to sample data, this is the local instrumental variable (LIV) estimator of Heckman and Vytlacil (1999). We can recover the return to schooling for persons indifferent between  $S = 1$  and  $S = 0$  at all margins of  $U_S$  within the empirical support of  $P(Z)$  (conditional on  $X$ ). Notice that persons with a high mean scale utility function  $P(Z)$  identify the return for those with a *high* value of  $U_S$ , i.e., a value of  $U_S$  that makes persons *less* likely to participate in schooling. Marginal increases in  $P(Z)$  starting from high values of  $P(Z)$  induce those individuals with high  $U_S$  values into schooling. Those with low values of  $U_S$  are already in school for such values of  $P(Z)$  so that a marginal increase in  $P(Z)$  starting from a high value has no affect on those with low values of  $U_S$ . We can identify returns at all quantiles of  $U_S$  within the support of the distribution of  $P(Z)$ . Thus we can determine which persons (identified by the quantile of the unobserved component of

---

<sup>4</sup>We are assuming for this derivation that  $U_1 - U_0$  is a continuous random variable. However, the result holds under more general conditions. See Heckman and Vytlacil (2001a, 2005) and Heckman, Urzua, and Vytlacil (2006).

the desire to go to college,  $U_S$ ) are induced to go into college ( $S = 1$ ) by a marginal change in  $P(Z)$ .

As noted by Heckman, Urzua, and Vytlacil (2006), the probability of selection ( $P(Z)$ ), sometimes called the “propensity score,” plays a central role in instrumental variable models that satisfy the independence and monotonicity conditions of Imbens and Angrist (1994) (or equivalently that are characterized by the latent variable discrete choice model of equation (3)). Aggregating the instruments into the scalar index  $P(Z)$  enlarges the range of values over which we can identify MTE in comparison to using each instrument one at a time. One can also determine the contribution of each instrument to identifying different regions of the MTE function.

Heckman and Vytlacil (1999, 2001a, 2005, 2007a,b) establish that standard summary measures of the return to college such as the average return to college in the population ( $E(\beta|X)$ ), and the average return to college among those who attend college ( $E(\beta|X, S = 1)$ ), can be expressed as different weighted averages of the MTE. They show that treatment parameter  $j$ ,  $\Delta_j$ , can be written as a weighted average of the MTE:

$$\Delta_j(x) = \int_0^1 \text{MTE}(x, u_S) h_j(x, u_S) du_S. \quad (7)$$

See Table A-1 in the attached Web Appendix for the weights for different treatment parameters in the literature. Heckman and Vytlacil also show that the standard IV estimator is a weighted average of the MTE with estimable weights, i.e., for instrument  $Z^k$ ,

$$\text{IV}_k(x) \equiv \frac{\text{Cov}(Y, Z^k | X = x)}{\text{Cov}(S, Z^k | X = x)} = \int_0^1 \text{MTE}(x, u_S) h_k(x, u_S) du_S, \quad (8)$$

where again the weights can be consistently estimated from sample data. Observe that if  $\text{MTE}(x, u_S)$  does not depend on  $x$ , all instruments estimate the same parameter which is  $\beta(x)$ , the average treatment effect.<sup>5</sup> In this case, marginal and average ex post returns are equal and all IV estimate a common policy effect that is the same no matter how  $P(Z)$  is varied by policy shifts. The instrumental variable weights arise because different values of the instruments identify different segments of the MTE and IV averages out the different values using weight  $h_k(x, u_S)$ . The explicit formula for the IV weight is given in Appendix Table A-1.<sup>6</sup> In general, the IV weights are different from the treatment parameter weights.

---

<sup>5</sup>The weights integrate to one no matter what the instrument.

<sup>6</sup>The Web Appendix shows the relationship between LATE and MTE. The former is the integral of the latter.

## 2.1 Policy Relevant Treatment Effects and Marginal Policy Relevant Treatment Effects

Following Heckman and Vytlacil (2001b, 2005, 2007b), we consider a class of policies that change  $P(Z)$ , the probability of participation in the program, but that do not affect potential outcomes or the unobservables related to the selection process,  $(Y_0, Y_1, V)$ .<sup>7</sup> An example from the literature on the economic returns to schooling would be policies that change tuition or distance to school but that do not directly affect potential wages (Card, 2001).<sup>8</sup>

Let  $S^*$  be the treatment choice that would be made after the policy change. Let  $P^*$  be the corresponding probability that  $S^* = 1$  after the policy change.  $S^*$  is defined by  $S^* = \mathbf{1}[P^* \geq U_S]$ . Let  $Y^* = S^*Y_1 + (1 - S^*)Y_0$  be the outcome under the alternative policy. Heckman and Vytlacil (2005, 2007b) show that the mean effect of going from a baseline policy to an alternative policy per net person shifted is the Policy Relevant Treatment Effect (PRTE), defined when  $E(S) \neq E(S^*)$  as

$$\begin{aligned} & \frac{E(Y \mid \text{Alternative Policy}) - E(Y \mid \text{Baseline Policy})}{E(S^* \mid \text{Alternative Policy}) - E(S \mid \text{Baseline Policy})} \\ &= \frac{E(Y^*) - E(Y)}{E(S^*) - E(S)} = \int_0^1 \text{MTE}(u_S) \omega_{\text{PRTE}}(u_S) du_S \end{aligned}$$

where

$$\omega_{\text{PRTE}}(u_S) = \frac{F_{P^*}(u_S) - F_P(u_S)}{E_{F_{P^*}}(P) - E_{F_P}(P)},$$

where  $F_{P^*}$  and  $F_P$  are the distributions of  $P^*$  and  $P$ , respectively, and we suppress  $X$  to simplify notation. The condition  $E(S) \neq E(S^*)$  is consistent with the policy having a non-monotonic effect on participation as long as the fraction switching into treatment is not exactly offset by the fraction switching out of treatment. The PRTE parameter gives the normalized effect of a change from a baseline policy to an alternative policy and depends on the alternative being considered.<sup>9</sup>

As shown by the above equation, PRTE depends on the policy change only through the distribution of  $P^*$  after the policy change. In other words, given our assumptions,  $F_{P^*}$  is sufficient to summarize everything about the proposed policy change that is relevant for calculating the average effect of the policy change. The PRTE maps the proposed policy change (corresponding to a distribution of  $P^*$ ) to the resulting per-person change in outcomes. In general, the PRTE for a

<sup>7</sup>This restriction can be relaxed to a weaker policy invariance assumption for the distribution of  $(Y_0, Y_1, V)$ , see Heckman and Vytlacil (2005, 2007b).

<sup>8</sup>We ignore general equilibrium effects.

<sup>9</sup>The PRTE can be interpreted as an economically more explicit version of Stock's (1989) nonparametric policy analysis parameter for a class of policy interventions with explicit agent preferences where the policies evaluated operate solely on agent choice sets.

proposed policy change of interest will differ from the probability limit of an IV estimator. The change in the distribution of  $P$  induced by the policy in general differs from the change induced by an instrument, unless the instrument is the policy change. For example, policy variations in tuition will not in general have the same effects as instrument variations in distance to college.

The PRTE is defined for a discrete change from a baseline policy to a fixed alternative. As noted in Carneiro, Heckman, and Vytlacil (2009), identifying it in any sample can be a challenging task because it often requires that the support of  $P(Z)$  be the full unit interval. Below, we show that our estimated  $P(Z)$  does not satisfy this requirement. Instead we estimate a marginal version of the PRTE parameter (MPRTE) that corresponds to a marginal change from a baseline policy. It is less empirically demanding to estimate yet answers an economically interesting question. The marginal version of the PRTE depends on the nature of the perturbation that defines the marginal change. For example, a policy change that subsidizes tuition by a fixed amount has different effects than a policy change that subsidizes tuition by a fixed proportion. The limits of these two policies for infinitesimally small subsidies are different. (Carneiro, Heckman, and Vytlacil, 2009.)

More formally, we define the MPRTE as follows. Consider a sequence of policies indexed by a scalar variable  $\alpha$ , with  $\alpha = 0$  denoting the baseline, status quo policy. We associate with each policy  $\alpha$  the corresponding fitted probability of schooling  $P_\alpha$ , where  $P_0 = P(Z)$ , the baseline propensity score. For each policy  $\alpha$  we define the corresponding PRTE parameter for going from the baseline status quo to policy  $\alpha$ . We define the MPRTE as the limit of such a sequence of PRTEs as  $\alpha$  goes to zero. We will consider the following examples of such sequences of policies: (i) a policy that increases the probability of attending college by an amount  $\alpha$ , so that  $P_\alpha = P_0 + \alpha$  and  $F_\alpha(t) = F_0(t - \alpha)$ ; (ii) a policy that changes each person's probability of attending college by the proportion  $(1 + \alpha)$ , so that  $P_\alpha = (1 + \alpha)P_0$  and  $F_\alpha(t) = F_0(\frac{t}{1+\alpha})$ ; and (iii) a policy intervention that has an effect similar to a shift in one of the components of  $Z$ , say  $Z^{[k]}$ , so that  $Z_\alpha^{[k]} = Z^{[k]} + \alpha$  and  $Z_\alpha^{[j]} = Z^{[j]}$  for  $j \neq k$ . For example, the  $k$ th element of  $Z$  might be college tuition, and the policy under consideration subsidizes college tuition by the fixed amount  $\alpha$ . In each of these three cases, we consider the corresponding PRTE for going from the status quo to policy  $\alpha$ , and consider the limit of such PRTEs as  $\alpha$  goes to zero. These limits in general differ from IV estimates. Just as IV is a weighted average of the MTE, as in equation (8), there is a similar expression for average marginal policy changes that weights up the MTE by the proportion of persons induced to change by the policy. In general, the weights are different for IV and MPRTE. (See Table 1 in the Appendix and Table 1 in the text, respectively.)

The MPRTE is the appropriate parameter with which to conduct cost-benefit analysis of marginal policy changes. In our empirical work we contrast our estimates of the MPRTE with estimates from conventional IV estimates of the return to college.

Carneiro, Heckman, and Vytlacil (2009) relate the MPRTE to the Average Marginal Treatment

Effect (AMTE): the mean benefit of treatment for people indifferent between participation in treatment and non-participation. There are technical issues that arise in identifying the marginal gain to persons in indifference sets that arise from the thinness of the indifference sets. For conventional economic models, the probability that anyone is indifferent is exactly zero. Different ways to approximate the indifference set  $P(Z) = U_S$  through limit operations determine different values of the AMTE. The effect of a marginal policy change for a particular perturbation of  $P(Z)$  is the same as the average effect of treatment for those who are arbitrarily close to being indifferent between treatment or not, according to a given metric  $m(P, U_S)$  measuring the distance between  $P(Z)$  and  $U_S$ . This parameter is defined as  $AMTE = \lim_{e \rightarrow 0} E[Y_1 - Y_0 | m(P, U_S) \leq e]$ . For the three examples of MP RTE previously discussed, the corresponding metrics defining the AMTE are respectively: (i)  $m(P, U_S) = |F_V(P) - F_V(U_S)| = |\mu_S(Z) - V|$ ; (ii)  $m(P, U_S) = |P - U_S|$ ; (iii)  $m(P, U_S) = \left| \frac{P}{U_S} - 1 \right|$ . Table 1 shows the different weights associated with the different definitions of the Average Marginal Treatment Effect and the associated MP RTE.

## 2.2 Practical Issues In Estimating the MP RTE

In practice, it is very difficult to condition on  $X$  non-parametrically, especially when  $X$  includes many variables (as is the case in our empirical work). Therefore, in our empirical work we proceed by imposing an additional assumption, which is standard in the literature applying both IV and selection models to estimate the returns to schooling: that  $(X, Z)$  is independent of  $(U_0, U_1, U_S)$  (as opposed to the weaker assumption that  $(U_0, U_1, U_S)$  is independent of  $Z$  given  $X$ ). Under this assumption the MTE is additively separable in  $X$  and  $U_S$ . One important consequence of imposing this assumption is that the MTE is identified over the unconditional support of  $P$ , as opposed to the support of  $P$  conditional  $X$ . This result is illustrated graphically Figure 3 which we discuss in Section 3.3 below.

In our empirical analysis, we work with linear-in-the-parameters versions of  $\mu_1(X)$ ,  $\mu_0(X)$ , and  $\mu_S(Z)$ :  $\mu_1(X) = X\delta_1$ ,  $\mu_0(X) = X\delta_0$ ,  $\mu_S(Z) = Z\gamma$ . In this case,

$$E(Y | X = x, P(Z) = p) = x\delta_0 + px[\delta_1 - \delta_0] + K(p), \quad (9)$$

where  $K(p) = E(U_1 - U_0 | S = 1, P(Z) = p)$  can be estimated nonparametrically. It is straightforward to estimate the levels and derivatives of  $E(Y | X = x, P(Z) = p)$  and their standard errors using the methods developed in Heckman, Ichimura, Smith, and Todd (1998).

An alternative to the semi-parametric model just described is to impose parametric assumptions on the joint distribution of  $(U_0, U_1, V)$  and derive the expression for the MTE (see Heckman, Tobias, and Vytlačil, 2001, and Aakvik, Heckman, and Vytlačil, 2005). Below we also present estimates based on the assumption that  $(U_0, U_1, V)$  is jointly normally distributed, and independent

of  $(X, Z)$ . Following conventions in discrete choice analysis (McFadden, 1974), we normalize the variance of  $V$  to 1. In this case:

$$\begin{aligned}
\text{MTE}(x, u_S) &= x(\delta_1 - \delta_0) + E(U_1 - U_0 | U_S = u_S) \\
&= x(\delta_1 - \delta_0) + E(U_1 - U_0 | V = \Phi^{-1}(u_S)) \\
&= x(\delta_1 - \delta_0) - (\sigma_{1V} - \sigma_{0V}) \Phi^{-1}(u_S)
\end{aligned} \tag{10}$$

where  $\sigma_{1V} = \text{Cov}(U_1, V)$ ,  $\sigma_{0V} = \text{Cov}(U_0, V)$  and where  $\Phi^{-1}(\cdot)$  is the inverse of the standard normal cumulative distribution function. The parameters  $(\delta_0, \delta_1, \sigma_{1V}, \sigma_{0V})$  and their standard errors can be estimated by maximum likelihood with the resulting parameter estimates plugged into equation (10) to form an estimate of MTE.

### 3 Estimates of the MTE and Comparison of Marginal Returns, Policy Relevant Returns, and IV Estimands

#### 3.1 Data

This section reports estimates of the MTE using a sample of white males from the National Longitudinal Survey of Youth of 1979 (NLSY). The data are described in the attached Web Appendix. Individuals are separated into two groups:  $S = 0$  (high school dropouts and high school graduates) and  $S = 1$  (individuals with some college, college graduates and post-graduates). Below we study the sensitivity of our estimates to alternative definitions of schooling groups, alternative specifications of the model, and alternative samples. Schooling is measured in 1991 (individuals are between 28 and 34 years of age in 1991).

The variables in  $Y$ ,  $S$ ,  $X$  and  $Z \setminus X$  (the instruments or identifying exclusion restrictions) are presented in Table 2, together with the main papers which have previously used these instruments. They are (a) the presence of a four year college in the county of residence at age 14 as a measure of distance to college, (b) local wage in the county of residence at age 17, (c) local unemployment in the state of residence at age 17, and (d) average tuition in public 4 year colleges in the county of residence at age 17.<sup>10</sup>

Distance to college was first used as an instrument for schooling by Card (1995) and was subsequently used by Kane and Rouse (1995), Kling (2001), Currie and Moretti (2003) and Cameron and Taber (2004). Cameron and Taber (2004) and Carneiro and Heckman (2002) show that distance to college in the NLSY79 is correlated with a measure of ability (AFQT). In this paper, we

---

<sup>10</sup>We have constructed both county and state measures of unemployment, but our state measure has better predictive power for schooling (perhaps because of less measurement error), and therefore we choose to use it instead of county unemployment.

include this measure of ability in the outcome equation.

Cameron and Heckman (1998, 2001) and the papers they cite emphasize the importance of controlling for local labor market characteristics (see also Cameron and Taber, 2004). If local unemployment and local earnings at age 17 are correlated with the unobservables in earnings equations in the adult years, our measures of local labor market conditions would not be valid instruments. To mitigate this concern, we have included measures of permanent local labor market conditions (which we define as the average earnings and unemployment between 1973 and 2000 for each location of residence at 17) both in the selection and outcome equations. Effectively, we only use local business cycle innovations as instruments. This is similar to the procedure used by Cameron and Taber (2004). Further, in the outcome equations we also include the average log earnings in the county of residence in 1991, and the average unemployment rate in the state of residence in 1991.<sup>11</sup>

Tuition is used to predict college attendance in Cameron and Heckman (1998, 2001) and Kane and Rouse (1995). We control for AFQT and maternal education in all of our models. These variables are likely to be highly correlated with college quality. We use these variables to account for any correlation between our measure of tuition (which corresponds only to 4 year public colleges) and college quality. In order to examine the sensitivity of our estimates to the choice of instruments, we estimate models with and without local unemployment, and with and without tuition.

Included among  $X$  and  $Z$  in the linear-in-parameter representations are linear and quadratic terms in AFQT, mother's education, number of siblings, permanent local earnings, and permanent local unemployment, as well as a dummy variable indicating urban residence at age 14, and cohort dummies. The four exclusion restrictions or instruments enter  $\mu_S(Z)$  and not the outcome equations  $\mu_1(X)$  or  $\mu_0(X)$ . They are interacted with AFQT, maternal education, and number of siblings.<sup>12</sup> In addition, three variables are included in the outcome equations but not the selection equation: years of experience in 1991 (and its square), earnings in the county of residence in 1991, and unemployment in the state of residence in 1991. Given that these variables are only realized in

---

<sup>11</sup>As argued in Cameron and Taber (2004), the sign of the total impact of these variables on schooling choice is theoretically ambiguous. Local labor market conditions can influence schooling through two possible channels. On the one hand, better labor market conditions increase the opportunity costs of schooling, and reduce educational attainment. On the other hand, better labor market conditions lead to an increase in the resources of credit constrained households, and therefore promote educational attainment.

<sup>12</sup>The total sample size is 1747 (882 with  $S = 0$  and 865 with  $S = 1$ ). Table A-3 in the Appendix documents that individuals who attend college have on average a 34% higher wage than those who do not attend college. They also have 3.25 less years of work experience since they spend more time in school (on average they have 4 additional years of completed schooling). The scores on a measure of cognitive ability, the Armed Forces Qualifying Test (AFQT), are much higher for individuals who attend college than they are for those who do not. Those who only attend high school have less educated mothers, come from larger families, and are less likely to have grown up in an urban area and in an area with a public four year college than individuals who attend college. They face higher tuition in the areas where they grew up. Local labor market variables are not much different between these two groups of individuals, independently of the time of measurement.

1991 and that we condition on earlier values of these variables, it is natural to assume the residualized variables do not enter the individuals' information sets at the time individuals make college decision, which for most of them takes place more than 12 years earlier.<sup>13</sup>

Table 3 presents estimates of the parameters of a logit model for schooling choice. We provide estimates of the average marginal derivatives of each variable in the choice model (the coefficients are in Table A-4 in the Appendix). The instruments are (jointly) strong predictors of schooling, as are mother's education, AFQT, number of siblings, and permanent local earnings in the county of residence at age 17.

The tests for selection on returns ( $\beta$  correlated with  $S$  in equation (1), also known as selection on gains), developed and applied in Heckman, Schmierer, and Urzua (2009), test whether the MTE is constant in  $u_S$  ( $\beta$  uncorrelated with  $S$ ), or whether it varies with  $u_S$  ( $\beta$  correlated with  $S$ ). Given equations (5) and (6), a simple test of selection on gains consists of estimating equation (9), specifying  $K(P)$  to be a polynomial in  $P$  ( $P$  is estimated using a logit), and testing whether the coefficients on the polynomial terms of order higher than 1 are jointly statistically significant.<sup>14</sup>

The results of this test are in Table 4A. In each column of the table we specify a polynomial in  $P$  of orders 2 through 5. For each specification we present the p-values of joint tests that the coefficients on the terms of order higher than 1 in each polynomial are equal to zero (rejection would be an indication that  $K(P)$  is a nonlinear function of  $P$ ). We account for the fact that we test multiple hypotheses simultaneously (Romano and Wolf, 2005) by constructing an adjusted critical value, which we compare to the lowest p-value across the columns of this table (see Heckman, Schmierer, and Urzua, 2009). Using this test we reject that the MTE is constant in  $u_S$  — agents in our sample select in part on ex post gains to schooling.

### 3.2 Estimating the MTE and Marginal Policy Effects using a Normal Selection Model

The traditional approach to estimating the model of equations (2) and (3) specifies a parametric joint distribution for  $(U_0, U_1, V)$ , usually that  $(U_0, U_1, V)$  are jointly normal distributed and independent of  $(X, Z)$ , and estimates the outcome and choice equations together using the method of maximum likelihood (e.g., Björklund and Moffitt, 1987). Although our primary empirical results are from a semi-parametric method, the results based on a parametric normal model is a useful benchmark against which to compare our estimates from less functional form dependent estimators. The parametric specification is less flexible than our semi-parametric specification, but the

---

<sup>13</sup>Below we also present results where instruments are not interacted with  $X$ , and where these experience and local labor market conditions in 1991 are not excluded from the selection equation. The results are very similar to the ones we obtain in our main specification, although with larger standard errors in the first case.

<sup>14</sup>The test assumes that  $(X, Z)$  are statistically independent of  $(U_0, U_1, U_S)$ .

resulting estimates are much more precise.

Maximum likelihood estimates of the parameters  $\delta_0, \delta_1, \gamma$  and their standard errors are presented in Table A-5 in the Web Appendix. The MTE for this model is equation (10). A simple test of whether the slope of the MTE is zero (i.e., individuals do not select into college based on variability in  $\beta$ ) is a test of whether  $\sigma_{1V} - \sigma_{0V} = 0$ . We estimate that  $\sigma_{1V} - \sigma_{0V} = -0.2388$  with a standard error of 0.0982, so we reject this hypothesis (p-value = 0.0150). This supports the inference obtained from Table 4A without the joint normality assumption.

Figure 1 plots the estimated MTE with 90% confidence bands, evaluated at mean values of  $X$  (we obtain annualized estimates of the returns to college by dividing the MTE by 4, which is the average difference in years of schooling for those with  $S = 1$  and those with  $S = 0$ ). The MTE is declining and precisely estimated. The most college worthy persons in the sense of having high gross returns are more likely to go to college (they have low  $U_S$ ). Individuals choose the schooling sector in which they have comparative advantage. The magnitude of the heterogeneity in returns on which agents select is substantial: returns can vary from -15.6% (for high  $U_S$  persons, who would lose from attending college) to 28.8% per year of college (for low  $U_S$  persons), although we cannot reject that the negative values of the MTE are statistically significantly different from zero.<sup>15</sup> The magnitude of total heterogeneity is likely to be even higher since the MTE is the average gain at that quantile of desire to attend college – in general, there will be a distribution of returns centered at each value of the MTE. Furthermore, once we account for variation in  $X$  and its impact on returns through  $X(\delta_1 - \delta_0)$ , we observe returns as low as -31.56% and as high as 51.02%.

Using the weights presented in Appendix Table A-1, we can construct the standard treatment parameters from the MTE. We present the results in the first column of Table 5 (standard errors are bootstrapped). These include marginal returns to the three different policies considered in Table 1 (MPRTE), which are all below the return to the average student ( $IT = E(\beta|S = 1)$ ), and the IV estimate. But it is not clear if these estimates are reliable given the strong normality assumption used to generate them. We next corroborate these estimates of marginal returns using a more robust semiparametric approach.

### 3.3 Estimating the MTE and Marginal Policy Effects using Local Instrumental Variables

An alternative and more robust approach for estimating the MTE estimates  $E(Y|X, P(Z) = p)$  semi-parametrically and then computes its derivative with respect to  $p$ , as shown in the analysis of equations (5) and (6). If all we are willing to assume is that  $(U_0, U_1, V)$  is independent of  $Z$  given

---

<sup>15</sup>One unattractive feature of the normal model is that (for our estimates of  $\sigma_{1V}$  and  $\sigma_{0V}$ )  $MTE(x, 0) = +\infty$  and  $MTE(x, 1) = -\infty$ . In order to get finite values at the extremes of the normal MTE we restrict the support of  $U_S$  to be between 0.0001 and 0.9999.

$X$  then it is only possible to estimate the MTE over the support of  $P$  conditional on  $X$ . Figure 2 plots  $f(P|X)$ , the density of  $P$  given  $X$  ( $P$  is estimated by a logit). Since  $X$  is multidimensional, we use an index of  $X$  that is described in detail below. It is striking how small the support of  $P$  is for each value of the  $X$  index. It is not possible to estimate MTE over the full unit interval, and as a consequence, it is not possible to estimate conventional treatment parameters such as the average treatment effect ( $E(\beta)$ ) or the effect of treatment on the treated ( $E(\beta | S = 1)$ ). However, it is still possible to estimate MP RTE, since this parameter only puts positive weight over sections of the MTE that are identified within the support of  $f(P | X)$ .

Empirically, it is very difficult to apply the procedure described in section 2 while conditioning on  $X$  non-parametrically. Therefore, we proceed by invoking the stronger assumption that  $(X, Z)$  is independent of  $(U_0, U_1, U_S)$ . Under this assumption, MTE is identified over the marginal support of  $P(Z)$ , and thus it is only necessary to investigate the marginal support of  $P(Z)$  as opposed to the support of  $P(Z)$  given  $X$ . The support of the estimated  $P(Z)$  is shown in Figure 3, and it is almost the full unit interval. We trim observations for which the estimated  $P(Z)$  is below 0.0324 or above 0.9775, which are the minimum and maximum values of  $P$  for which we have common support.<sup>16</sup>

The parameters of equation (9) can be estimated by a partially linear regression of  $Y$  on  $X$  and  $P(Z)$ . We proceed in two steps. The first step is construction of the estimated  $P(Z)$  and the second step is estimation of  $\delta_1$  and  $\delta_0$  using the estimated  $P(Z)$ . The first step is carried out using a logit regression of  $S$  on  $Z$ . Our specification is quite flexible, and alternative functional form specifications for the choice model (e.g., probit) produce similar results to the ones reported here. In the second step we use the Robinson (1988) method for estimating partially linear models as extended in Heckman, Ichimura, and Todd (1997).<sup>17</sup> Estimates of  $\delta_1$  and  $\delta_0$  are presented in Web Appendix Table A-6.

Next consider estimation of  $K(P(Z))$ . Equation (9) implies that

$$E(Y - X\delta_0 - P(Z)X[\delta_1 - \delta_0] | P(Z)) = K(P(Z)).$$

We thus use local polynomial regression of  $Y - X\hat{\delta}_0 - \hat{P}(Z)X[\hat{\delta}_1 - \hat{\delta}_0]$  on  $\hat{P}(Z)$  to estimate  $K(P(Z))$  and its partial derivative with respect to  $P(Z)$ . Local polynomial estimation not only provides a unified framework for estimating both a function and its derivative but also has a variety

<sup>16</sup>We define common support as the intersection of the support of  $P(Z)$  given  $D = 1$  and the support of  $P(Z)$  given  $D = 0$ . Restricting our empirical estimates to the common support leads us to delete 67 observations, corresponding to 4.35% of the sample.

<sup>17</sup>We run kernel regressions of each of the regressors on  $P$  using a bandwidth of 0.05. We compute the residuals of each of these regressions and then run a linear regression of  $Y$  on these residuals. Our results are robust to choices of bandwidth between 0.01 and 0.2.

of desirable properties in comparison with other available nonparametric methods.<sup>18</sup>

Figure 4 plots the component of the MTE that depends on  $U_S$ , with 90% confidence bands computed from the bootstrap.<sup>19</sup> We fix the components of  $X$  at their mean values in the sample. As above, we annualize the MTE. Our estimates show that, in agreement with the normal model,  $E(U_1 - U_0 | U_S = u_S)$  is declining in  $u_S$ , i.e., that students with high values of  $U_S$  have lower returns than those with low values of  $U_S$ .

Even though the semi-parametric estimate of the MTE has larger standard errors than the estimate based on the normal model, we still reject that its slope is zero. We have already discussed the rejection of the hypothesis that MTE is constant in  $u_S$ , based on the test results reported in Table 4A. But we can also directly test whether the semi-parametric MTE is constant in  $u_S$  or not. We evaluate the MTE at 26 points, equally spaced between 0 and 1 (with intervals of 0.04). We construct pairs of adjacent points (0-0.04, 0.08-0.12, 0.16-0.20, 0.24-0.28,...) and we take the mean of the MTE for each pair. These are local average treatment effects (LATEs) for different sections of the MTE. We compare adjacent LATEs. Table 4B reports the outcome of these comparisons. For example, the first column reports that

$$E(Y_1 - Y_0 | X = \bar{x}, 0 \leq U_S \leq 0.04) - E(Y_1 - Y_0 | X = \bar{x}, 0.08 \leq U_S \leq 0.12) = 0.0689.$$

The p-value of the test of the hypothesis that this difference is equal to zero is reported below this number and is 0.0240, which implies that we reject this hypothesis at conventional levels of significance.<sup>20</sup> This table shows that the slope of the MTE is negative and statistically significant

<sup>18</sup>Fan and Gijbels (1996) provide a detailed discussion of the properties of local polynomial estimators. In general, use of higher order polynomials may reduce the bias but increase the variance by introducing more parameters. Fan and Gijbels (1996) suggest that the order  $\pi$  of the polynomial be equal to  $\pi = \tau + 1$ , where  $\tau$  is the order of the derivative of the function of interest that we want to fit. That is, Fan and Gijbels (1996) recommend a local linear estimator for fitting a function and a local quadratic estimator for fitting a first-order derivative. Therefore, we use a local quadratic estimator of  $\partial K(p) / \partial p$ . We choose the bandwidth that minimizes the residual square criterion proposed in Fan and Gijbels (1996), which gives us a bandwidth of 0.322. Our results are robust to the choice of bandwidths between 0.1 and 0.4.

<sup>19</sup>Heckman, Ichimura, and Todd (1997) show that the bootstrap provides a better approximation to the true standard errors than asymptotic standard errors for the estimation of  $\beta_1$ ,  $\beta_0$ , and  $K(P)$  in a model similar to the one we present here. We use 250 bootstrap replications. Throughout the paper, in each iteration of the bootstrap we re-estimate  $P(Z)$  so all standard errors account for the fact that  $P(Z)$  is itself an estimated object.

<sup>20</sup>Given that we bootstrap the non-parametric MTE, we implement the following test. For each pair of adjacent LATEs, the null is that the two LATEs are equal, and the alternative is that they are different. We construct 250 bootstrap replications of the MTE, evaluated at mean values of  $X$ . The MTEs are evaluated on 26 equally spaced points on a grid (between 0 and 1). Let  $LATE^A - LATE^B$  be the difference between two adjacent LATEs ( $A$  and  $B$ ), and let  $LATE_b^A - LATE_b^B$  be  $b^{\text{th}}$  bootstrap replication of this difference. Then we compute the following statistics:  $T = |LATE^A - LATE^B|$  (the absolute value of the difference between two adjacent LATEs) and  $T_b = |(LATE_b^A - LATE_b^B) - (LATE^A - LATE^B)|$  (the recentered absolute value of the difference between two adjacent LATEs). The p-value of the test is the proportion of bootstrap replications for which  $T_b > T$ .

A p-value for a joint test is also possible to construct by constructing  $C = \sum_{j=1}^{J-1} (LATE^j - LATE^{j+1})^2$  and

(at a 10% level of significance) for values of  $U_S$  up to 0.76 (p-values are reported in the bottom row of the table), and it remains negative but statistically insignificant after that. This is further evidence that individuals select into college based on heterogeneous returns in realized outcomes, although the rejection is only strong in the left tail of the estimated MTEs.<sup>21</sup> A joint test that the difference across all adjacent LATEs is different from zero has a p-value of 0.0520.

$P$  only has support between 0.0324 and 0.9775, and thus it is not possible to estimate parameters which require full support such as  $E(\beta)$ ,  $E(\beta | S = 1)$ , and  $E(\beta | S = 0)$ . Estimation of such parameters is possible in the normal model only because of its parametric assumptions. Analysts often define such parameters as the objects of interest, even though they are very hard to identify,<sup>22</sup> and even though they are often not economically interesting.

In contrast, the MP RTE parameter not only answers interesting economic questions about marginal gains of specific policies, but it is also identified without support conditions beyond  $P(Z)$  being a continuous random variable since it only requires estimating the MTE within the support of the data (see Carneiro, Heckman, and Vytlačil, 2009). The second column of Table 5 presents estimates of three different versions of the MP RTE where the policy considered is either a marginal change in tuition or a marginal change in  $P$ . The estimates are obtained in the following way. First we construct different weighted averages of the MTE by applying the weights of Table 1. Recall, however, that these weights are defined conditional on  $X$  and they define parameters conditional on  $X$ . Therefore, after computing each of these parameters for each value of  $X = x$ , we need to integrate them against the appropriate distribution of  $X$ .<sup>23</sup>

It is informative to visualize the weights behind each parameter, which show us why some parameters are higher or lower than others. Figure 5 graphs the weights on  $E(Y_1 - Y_0 | X, U_S = u_S)$  for the three MP RTE parameters in Table 5, all evaluated at mean  $X$ . While the MP RTE weights for the first two policies ( $Z_\alpha^k = Z^k + \alpha$  and  $P_\alpha = P + \alpha$ ) weight mainly the middle section of the MTE, the third policy ( $P_\alpha = (1 + \alpha)P$ ) overweights individuals with high levels of  $U_S$  because its

---

$C_b = \sum_{j=1}^{J-1} [(LATE_b^j - LATE_b^{j+1}) - (LATE^j - LATE^{j+1})]^2$ , where  $J$  is the number of LATEs taken (12 in our case). The p-value of the test is the proportion of bootstrap replications for which  $C_b > C$ .

<sup>21</sup>This and the other tests assume the validity of the instruments. If the instruments are not valid, these test results could be a consequence of the invalidity of the instruments.

<sup>22</sup>One alternative is to construct bounds, following Heckman and Vytlačil (2000). For example, in our data the lower bound on ATE is 0.0411 and the upper bound is 0.1043 (assuming a minimum value for the hourly wage of \$1 and a maximum value of \$100). We have also computed approximations to  $E(\beta)$ ,  $E(\beta | S = 1)$ , and  $E(\beta | S = 0)$ , where we rescale the weights in Table 1 to integrate to one over the region  $[0.0324; 0.9775]$ . These estimates are respectively (bootstrapped standard errors in parenthesis): 0.0815 (0.0454), 0.2420 (0.0713), and -0.0662 (0.0819).

<sup>23</sup>Since  $X$  is a high dimensional vector it is not computationally feasible to condition on it. Therefore, as an approximation, we condition instead on an index of  $X$ :  $X(\delta_1 - \delta_0)$ . A better approach would be to estimate the index using, for example, semiparametric least squares (SLS; see Ichimura, 1993), exploiting that  $f(P|X) = f(P|X\theta) \Rightarrow E(P|X) = E(P|X\theta)$ . Since this procedure is computationally very intensive it is not feasible to compute standard errors from it. We show below that the point estimates we obtain when estimating this index by SLS are very similar to the ones we get with the index we use.

effect on enrollment is larger for those with already high levels of  $P$ .<sup>24</sup>

The IV estimate, presented in the second to the last row of Table 5, is 0.0951. We use  $P(Z)$  as the instrument, but it is possible to construct IV estimates for other combinations of instruments (see Table A-7 in the Appendix). IV does not correspond to any of the MP RTE parameters that we consider, and it is particularly far from MP RTE in the case of the third policy. Figure 5 shows the sharp difference in the MTE weights for IV/LATE and the third of the MP RTE parameters, evaluated at mean  $X$ .

Notice that both MP RTE and LATE correspond to some marginal effect (see Imbens, 2009, for arguments for using LATE). However, LATE only estimates the policy effect of interest if the instrument variation corresponds exactly to the policy variation. For a specific policy of interest LATE can be widely off the mark.<sup>25</sup>

One benefit of our approach over the LATE approach is that it enables us to determine what portion of the MTE each instrument in  $Z \setminus X$  identifies, i.e., it enables analysts to identify the quantiles of  $U_S$  that each instrument traces out. Thus in our approach, the margin identified by variation in each instrument is clearly identified. In the LATE approach that does not specify an explicit choice equation, the margin identified by variation in an instrument is not clearly defined.

Figure 6 shows the density of  $P(Z)$  when we fix the variables in  $X$  at their mean values and vary the instruments one at a time. This is the approach required to secure estimates if we condition on  $X$  and do not invoke independence between  $X$  and  $(U_0, U_1, V)$ . This exercise informs us about what margin each instrument identifies under more general conditions. It also shows how far we expand the support of  $P(Z)$  (and therefore, the support of  $U_S$  over which we can estimate the MTE) by using multiple instruments simultaneously, as opposed to using them one at a time. To generate the graph labeled “Distance,” we not only fix  $X$  at its mean, but we also fix all the other instruments at their mean values. Because the distance variable only takes two values, the density of  $P(Z)$  in this case only has two mass points. The line labeled “Wage” corresponds to the density of  $P(Z)$  we obtain when all variables except local wage at 17 are kept at their mean values, the line labeled “Unemp.” is generated by varying only local unemployment at 17, and the line labeled “Tuition” is generated by varying only local tuition at 17. Finally, the line labeled “All” is the density of  $P(Z)$  when all the instruments are allowed to vary and the variables in  $X$  are fixed at their mean values. Each instrument has different support, so if we were to use each instrument in isolation at mean  $X$  we would only be able to identify a small section of the MTE. When we allow all the instruments to vary simultaneously we get larger support for the MTE, but it is still not close

<sup>24</sup>Throughout the paper, we refer to the MP RTE of the policy  $Z_\alpha^k = Z^k + \alpha$  as a short hand for the limit as  $\alpha \rightarrow 0$  of the PRTE parameters defined by  $Z_\alpha^k = Z^k + \alpha$ , and likewise with the MP RTE for  $P_\alpha = P + \alpha$  and  $P_\alpha = (1 + \alpha)P$ .

<sup>25</sup>In fact, the IV estimate is a much better approximation to either of the other two MP RTE parameters, although the differences are still substantial (but not statistically significant). This approximation implicit in the estimates depends on the weights graphed in Figure A-1.

to full support for  $P(Z)$ . This analysis makes clear which instruments contribute to identifying which portions of the MTE.

### 3.4 Sensitivity to Alternative Models and Specifications

In order to examine the robustness of our estimates, it is useful to examine the sensitivity of our results to changes in specifications. The simplest way to do this is to examine how various summary measures of returns vary across specifications. It would be natural to present estimates of such parameters as the average treatment effect (ATE) ( $= E(\beta)$ ), the effect of treatment on the treated (TT) ( $= E(\beta | S = 1)$ ), and the effect of treatment on the untreated (TUT) ( $= E(\beta | S = 0)$ ), which put most of their weight in very different sections the MTE, and therefore should be sensitive to changes in the estimated MTE. Unfortunately, these parameters cannot be identified in our data, because the support of  $P$  is not quite the unit interval. However, the support of  $P$  is close to the unit interval. We report estimates of what ATE, TT and TUT would be if we restricted the weights to integrate to 1 in the support of the MTE ([0.0324;0.9775]). We call these parameters  $\widetilde{ATE}$ ,  $\widetilde{TT}$ , and  $\widetilde{TUT}$  (to distinguish them from ATE, TT, and TUT, which are not identified). In addition to these, we also consider (for parsimony, only) the first of the three definitions of MP RTE ( $Z_{\alpha}^k = Z^k + \alpha$ ), and the equivalent AMTE ( $|Z\gamma - V| < e$ ), shown in Table 5.

Results are reported in Tables 6A (where we focus mainly on choice of sample and specification of the outcome equations) and 6B (where we focus mainly on the specification of the choice equation). Column 1 of Table 6A presents estimates of the baseline specification, in addition to the  $p$ -values for two simple tests of selection on returns: a test of the null that  $MP RTE = \widetilde{TT}$  (does the marginal student attracted into schooling by the policy change have the same return as the average student in college?); and for a test of the null that there is no selection on returns in the normal model ( $H_0 : \sigma_{1V} - \sigma_{0V} = 0$ ).

Our baseline model has the important limitation since we restrict the schooling variable to take only two values. It is possible to extend this methodology to multiple levels of schooling (e.g., Heckman, Urzua, and Vytlačil, 2006, 2009; Heckman and Vytlačil, 2007b) but this requires multiple instrumental variables, one for each schooling transition. Even though the specification we use is common in the literature (e.g., Willis and Rosen, 1979, Taber, 2001, Carneiro and Heckman, 2002, Moffitt, 2009) it is still worthwhile to examine the robustness of our results to simple changes in it. To start with, note that other papers in the literature have either excluded high school dropouts from the sample (Willis and Rosen, 1979, Moffitt, 2009) or have imposed a simple model for the dropout decision (Taber, 2001). In column 2 of Table 6A we present estimates for a model where high school dropouts are excluded from the sample. The main difference, relatively to column 1, is an increase in the standard errors.

Column 3 presents a model where the sample is the same as in the baseline specification, but we include additional controls in the wage equations. The college equation includes a dummy for whether or not a person has some college but not a college degree (Willis and Rosen, 1979), and the high school equation includes a dummy for whether or a person has dropped out of high school (these dummies are assumed to be exogenous). The estimates of the return to schooling are similar to the ones in the baseline model, although slightly higher. However, the main patterns remain the same.

Table 6B considers changes in the specification of the decision equation. We start by noting that in our baseline specification there are three variables that are included in the wage equation but not in the college decision equations: years of experience, local earnings in the county of residence in 1991, and local unemployment in the county of residence in 1991. The assumption is that (conditional on all other controls) the agent does not have information about the effect of these variables on earnings at the time of the college decision typically made 8–15 years before and therefore they would have a zero coefficient in the selection equation. Alternatively, we could include these variables in the selection equation. The results from this exercise are shown in column 1 of Table 6B. The magnitude and main pattern of the estimates resembles that of the baseline model, although heterogeneity is less pronounced. In particular, the values for TT and TUT are not as far apart, because the MTE is flatter than in the baseline specification.

Recall from section 3.1 that the instruments (presence of college in area of residence, local wage and unemployment rate, local tuition) enter the college decision equation interacted with some of the control variables (AFQT, maternal education, number of siblings). It is natural to have such a specification because the effect of each of these instruments is likely to vary across different families. Furthermore, such a specification is helpful in achieving lower standard errors. However, one may worry that in such a specification what drives independent variation in college attendance is the set of controls (entering in a nonlinear way) as opposed to the instruments, even though we safeguard against this by having a very flexible specification of the wage equations. In column 2 of Table 6B we estimate a specification where none of the instruments is interacted with any other variable. The results are very similar to our baseline results, but with larger standard errors.

Columns 3 and 4 of Table 6B explore the sensitivity of our results to the choice of instruments. In the third column of Table 6B, we only use the instruments in Cameron and Taber (2004) (the presence of a college and local wage in the area of residence in adolescence), and in the fourth column of the table we exclude only tuition from the set of instruments in case it is correlated with college quality, even after controlling for AFQT and maternal education. The overall conclusion is that our main results are insensitive to the inclusion of tuition and of the local unemployment rate in the set of instruments, over and above the instruments used in Cameron and Taber (2004). The null hypothesis of no selection on returns is rejected in all of these samples, whether we use the

normality test or the test that  $\widetilde{TT} = \text{MPRTE}$ .<sup>26</sup>

Finally, the last column of Table 6B shows the point estimates of the main parameters which result from using an alternative method to estimate the index of  $X$  on which to condition when estimating the density of  $P$  conditional on  $X$   $f(P|X)$ . In particular, we estimate  $E(P|X)$  assuming a linear index in  $X$  and using semiparametric least squares (SLS; see Ichimura, 1993). We then use this index instead of the full  $X$  vector (and instead of an arbitrary index) to estimate  $f(P|X)$ , which we use to construct the parameter weights of Tables 1 and Appendix Table A-1. The estimates we obtain using this method are very similar to the point estimates of our baseline specification. However, they are computationally very demanding and it is not feasible to produce standard errors for our parameters using this method.

## 4 Summary and Conclusions

This paper estimates marginal returns to college when returns differ among individuals and persons select into economic activities based in part on their idiosyncratic return. Consistent with Heckman, Schmierer, and Urzua (2009), we find evidence that people select into schooling on the basis of realized returns to schooling. In general, marginal and average returns to college are not the same.<sup>27</sup> Conventional average return parameters and IV estimators are weighted averages of the marginal treatment effect (MTE). Unless the instruments are the policy changes of interest, these parameters do not answer well-posed policy questions. We show how to use the estimates from a local version of IV (LIV) to determine the marginal policy relevant treatment effect (MPRTE).

We show how to identify and estimate the MTE using a robust semi-parametric selection model. Focusing on a policy relevant question, we construct estimators based on the MTE to answer it, rather than hoping that a particular instrumental variable estimator happens to answer a question of economic interest.

It has been written “better LATE than nothing” (Imbens, 2009). We say that in addressing policy questions, “better MPRTE than LATE.” We also show that, using the MTE, we can identify the margins from which individuals induced into schooling by a change in an instrument originate.

We test for the importance of self-selection on ex post gains in the labor market. The data suggest that self-selection on gains is an empirically important phenomenon governing schooling choices, consistent with the analysis of Willis and Rosen (1979). Individuals sort into schooling on the basis of gains which are observed by the economist as well as unobserved (by the economist) variables. Marginal expansions of schooling programs produce marginal gains that are well below

---

<sup>26</sup>Except column 2 of Table 5B.

<sup>27</sup>This has implications for propensity score matching, which imposes that marginal and average returns are equal. See Heckman and Vytlačil (2007b).

average returns.

Comparing estimates from our semiparametric IV approach with estimates from a normal selection model of the sort used by Willis and Rosen (1979) and Björklund and Moffitt (1987), the semiparametric estimates produce an MTE with the same general shape consistent with diminishing returns to education for additional students, but with larger standard errors.

Table 2  
Definitions of the Variables Used in the Empirical Analysis

Variable	Definition
$Y$	Log Wage in 1991 (average of all non-missing wages between 1989 and 1993)
$S=1$	If ever Enrolled in College by 1991: zero otherwise
$X$	AFQT, <sup>a</sup> Mother's Education, Number of Siblings, Average Log Earnings 1979-2000 in County of Residence at 17, Average Unemployment 1979-2000 in State of Residence at 17, Urban Residence at 14, Cohort Dummies, Years of Experience in 1991, Average Local Log Earnings in 1991, Local Unemployment in 1991.
$Z \setminus X^b$	Presence of a College at Age 14 (Card, 1993, Cameron and Taber, 2004), Local Earnings at 17 (Cameron and Heckman, 1998, Cameron and Taber, 2004), Local Unemployment at 17 (Cameron and Heckman, 1998), Local Tuition in Public 4 Year Colleges at 17 (Kane and Rouse, 1995).

Note: <sup>a</sup>We use a measure of this score corrected for the effect of schooling attained by the participant at the date of the test, since at the date the test was taken, in 1981, different individuals have different amounts of schooling and the effect of schooling on AFQT scores is important. We use a version of the nonparametric method developed in Hansen, Heckman, et al. (2004). We perform this correction for all demographic groups in the population and then standardize the AFQT to have mean 0 and variance 1. See Table A-2. <sup>b</sup>The papers in parentheses are papers that previously used these instruments.

Table 3  
College Decision Model - Average Marginal Derivatives

	Average Derivative
CONTROLS ( $X$ ):	
Corrected AFQT	0.2826 (0.0114)***
Mother's Years of Schooling	0.0441 (0.0059)***
Number of Siblings	-0.0233 (0.0068)***
Urban Residence at 14	0.0340 (0.0274)
"Permanent" Local Log Earnings at 17	0.1820 (0.0941)**
"Permanent" State Unemployment Rate at 17	0.0058 (0.0165)
INSTRUMENTS ( $Z$ ):	
Presence of a College at 14	0.0529 (0.0273)**
Local Log Earnings at 17	-0.2687 (0.1008)***
Local Unemployment Rate at 17 (in %)	0.0149 (0.0100)
Tuition in 4 Year Public Colleges at 17 (in \$100)	-0.0027 (0.0017)*
Test for joint significance of instruments: $p$ -value	0.0001

Note: This table reports the coefficients and average marginal derivatives from a logit regression of college attendance (a dummy variable that is equal to 1 if an individual has ever attended college and equal to 0 if he has never attended college but has graduated from high school) on polynomials in the set of variables listed in the table and on cohort dummies (not reported). For each individual we compute the effect of increasing each variable by one unit (keeping all the others constant) on the probability of enrolling in college and then we average across all individuals. Bootstrapped standard errors (in parentheses) are presented below the corresponding parameters (250 replications). At the bottom we present  $p$ -value for the test of joint significance of coefficients on the instruments (bottom 12 variables of the table). Corrected AFQT corresponds to a standardized measure of the Armed Forces Qualifying Test score corrected for the fact that different individuals have different amounts of schooling at the time they take the test (see Hansen, Heckman and Mullen, 2004; see also the Web Appendix). This variable is standardized within the NLSY sample to have mean zero and variance 1. Local earnings and unemployment rates are averages across all individuals in the population residing in a given area (county for log earnings, state for unemployment), independent of age, gender, race, and skill level. For each location, "Permanent" local earnings and unemployment takes the average of each variable between 1979 and 2000 (and then assigns it to the location of residence at 17). \*\*\* Significant at 1%. \*\* Significant at 5%. \* Significant at 10%.

Joint P-Value	0.0520					

Notes: <sup>a</sup>The size of the test is controlled using a critical value constructed by the bootstrap method of Romano and Wolf (2005). <sup>b</sup>In order to compute the numbers in this table we construct groups of values of  $U_S$  and average the MTE within these groups, by computing  $E(Y_1 - Y_0|X = \bar{x}, U_S^L \leq U_S \leq U_S^H)$ , where  $U_S^L$  and  $U_S^H$  are the lowest and highest values of  $U_S$  for a given group. Then we compare the average MTE across adjacent groups and test whether the difference is equal to zero (using the bootstrap with 250 replications).

Table 5 - Returns to a Year of College

	Normal	Semi-Parametric
ATE	0.0670 (0.0378)	Not Identified

Normal - Selection Test	0.0150	0.1080	0.0560	0.0120	

Note: This table presents estimates of various returns to college for the semi-parametric model estimated on several samples: average treatment effect (ATE), treatment on the treated (TT), treatment on the untreated (TUT), and the marginal policy relevant treatment effect. The ATE, TT, and TUT estimates are computed such that the weights integrate to 1 in the interval [0.0324;0.9775]. The table also shows two tests of selection: the first tests whether  $TT=MPRTE$  in the semi-parametric model; the second tests whether  $COV(U_1, V) = COV(U_0, V)$  in the normal model. Standard errors are bootstrapped (250 replications). The last column of Table 6B shows estimates of the main parameters when semi-parametric least squares (SLS) is used to construct the index of  $X$  on which we condition on to estimate  $f(P|X)$  (estimates are presented without standard errors).

Figure 1: MTE Estimated from a Normal Selection Model

Notes: To estimate the function plotted here we estimate a parametric normal selection model by maximum likelihood. The figure is computed using the following formula:

$$\Delta^{\text{MTE}}(x, u_S) = \mu_1(x) - \mu_0(x) - (\sigma_{1V} - \sigma_{0V}) \Phi^{-1}(u_S)$$

where  $\sigma_{1V}$  and  $\sigma_{0V}$  are the covariances between the unobservables of the college and high school equation and the unobservable in the selection equation.  $X$  includes experience, current average earnings in the county of residence, current average unemployment in the state of residence, AFQT, mother's education, number of siblings, urban residence at 14, permanent local earnings in the county of residence at 17, permanent unemployment in the state of residence at 17, and cohort dummies. We also plot 90% confidence bands.

Figure 2: Support of  $P$  Conditional on  $X$

$P$  is the estimated probability of going to college. It is estimated from a logit regression of college attendance on corrected AFQT, mother's education, number of siblings, urban residence at 14, permanent earnings in the county of residence at 17, permanent unemployment in the state of residence at 17, cohort dummies, a dummy variable indicating the presence of a college in the county of residence at age 14, average log earnings in the county of residence at age 17, average state unemployment in the state of residence at age 17 (see Table 3).  $X$  corresponds to an index of variables in the outcome equation.

Figure 3: Support of  $P$  for  $S = 0$  and  $S = 1$

Notes:  $P$  is the estimated probability of going to college. It is estimated from a logit regression of college attendance on corrected AFQT, mother's education, number of siblings, urban residence at 14, permanent earnings in the county of residence at 17, permanent unemployment in the state of residence at 17, cohort dummies, a dummy variable indicating the presence of a college in the county of residence at age 14, average log earnings in the county of residence at age 17, average state unemployment in the state of residence at age 17 (see Table 3).

Figure 4:  $E(Y_1 - Y_0|X, U_S)$  with 90% Confidence Interval—Locally Quadratic Regression Estimates

Notes: To estimate the function plotted here we first use a partially linear regression of log wages on polynomials in  $X$ , interactions of polynomials in  $X$  and  $P$ , and  $K(P)$ , a locally quadratic function of  $P$  (where  $P$  is the predicted probability of attending college), with a bandwidth of 0.32.  $X$  includes experience, current average earnings in the county of residence, current average unemployment in the state of residence, AFQT, mother's education, number of siblings, urban residence at 14, permanent local earnings in the county of residence at 17, permanent unemployment in the state of residence at 17, and cohort dummies. The figure is generated by taking the coefficient in the linear term in  $P$  from  $K(P)$  and taking  $X$  at its average value multiplied by the coefficients on  $PX$ . 90% standard error bands are obtained using the bootstrap (250 replications).

Figure 5: Weights for three different versions of the MPRTE

Notes: The scale of the y-axis is the scale of the MTE, not the scale of the weights, which are scaled to fit the picture.

Figure 6: Support of  $P$  for fixed  $X$

Notes: This figures shows the density of  $P$  when we fix the variables in  $X$  at their mean values. In order to draw the line labeled Distance we not only fix  $X$  at its mean, but we also fix all the instruments at their mean values, except for the presence of a college at 14. The line labeled Wage corresponds to the density of  $P$  we obtain when all variables except local wage at 17 are kept at their mean values, and the line labeled Unemp is generated by varying only local unemployment at 17. Finally, the line labeled All is the density of  $P$  when all the instruments are allowed to vary and the variables in  $X$  are fixed at their mean values.

Figure 7: Weights for IV and MP RTE

Notes: The scale of the y-axis is the scale of the MTE, not the scale of the weights, which are scaled to fit the picture.
